Questions:	Answers:
1. What is a search tree in data structures?	A search tree is a tree-based data structure that efficiently inserts, locates and deletes within a data set. It is a hierarchical data structure that organizes and represents a parent-child relationship.
2. What are the different types of search algorithms in data structures? Differentiate each type of search.	The different types of search algorithms are linear search and binary search Linear search - it is used for unsorted arrays. It searches one by one comparison by each item to search with array elements. It takes O(n) time. Binary search - it is used for sorted arrays. It compares the array's middle element first and if that middle element has the same input, it returns. Otherwise it searches for either left or right based on its comparison result. It takes O(log n) time.
3. What operations/implementations can be performed using binary and linear search operations?	For linear search: The implementations used are finding unsorted data and retrieving it, searching linked lists, etc. For binary search: The implementations used are database indexing, debugging, network routing, file systems & libraries, etc.
4. What are the advantages in using a binary search tree as a data structure?	The advantages of using binary search tree are it is efficient when searching, ordered structure, dynamic insertion and deletion, balanced structure and doubly ended priority queue.
5. Give an example program using binary and linear search.	An example of programs that are using linear searches are unsorted data, small searches, etc and for binary searchers are databases, network routes and etc.
